ABSTRACT

In various applications in nuclear engineering and in particular in test reactors, heat removal is carried by single-phase axial flow. In these applications, we observe sharp changes in molecular viscosity while the density presents very limited changes. As a consequence, the Reynolds number increases often by 2-3 folds across the channel, with an inlet value often transitional. In these conditions, turbulence changes significantly across the length of the channel with redistribution and thinning of the boundary layers. This is different from acceleration as the effect of changes in density is negligible. We aim to characterize in detail this phenomenon.

In particular Nek5000, a spectral-element computational fluid dynamics (CFD) code, will be used to perform DNS of fluid flow in the transition regime for channel flow with varying viscosity. We set up a novel benchmark case: the channel is extended in the stream-wise direction up to 20pi. The viscosity is kept constant in the first 4pi region. This inlet region is used as a cyclic region to obtain a fully developed flow profile at the beginning of the ramping region. The ramping region (4pi -20pi) is defined as a transition region where the viscosity is linearly decreased along the channel. The flow is homogenous in the span-wise direction due to the periodic boundary conditions. Due to the cyclic and wall boundary conditions, the flow is non-homogenous in the stream-wise and wall-normal direction respectively.

In this study, specific focusS is given to the investigation of turbulence properties and structures in the near-wall region along the flow direction. Detailed turbulence budgets are collected and investigated. As expected, the results show that variation in the Reynolds across a channel does not cause an immediate change in the size of turbulent structures in the ramp region and a delay is in fact observed. Moreover, the results from the present study are compared with a correlation available in the literature for the friction velocity and as a function of the Reynolds-number.

NOMENCLATURE

- a Viscosity linear coefficient.
- C Contractioning parameter.
- F_{Ci} Delayed function of Cases i=I,II and III.
- R Relaxing parameter.
- Re Reynolds number.
- Re_{τ} Friction Reynolds number.
- u_{τ} Friction velocity.
- x Streamwise direction.
- y Vertical direction.
- z Spanwise direction.
- δ Height of the turbulence channel.
- δ_i Streamwise position where Region i starts, i=I,II and III.
- Λ Signal contribution in the delayed function.
- v Viscosity.
- τ_w Shear stress at the wall.

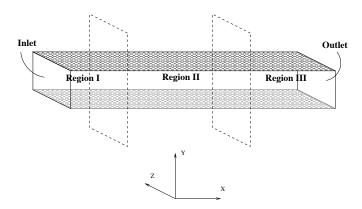

FIGURE 1: Geometry of the turbulence channel, the channel is divided into three different Regions.

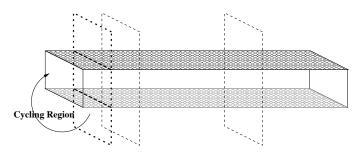

FIGURE 2: Cyclic region in the inlet.

INTRODUCTION

A schematic of the turbulence channels simulated are shown in Fig. 1. In this figure, Regions I, II and III are defined by two planes crossing the channel. A cycling region is implemented within Region I, Fig. 2. In this problem, the viscosity v is a function of x, i.e., the streamwise distance. This parameter has constants values of 1E-4 Pa.s and 5E-5 Pa.s along Regions I and III respectively, while in region II it decreases with respect to the inverse of x.

In the present work, three cases varying the length of Region II are studied. Cases I, II and III have their Region II length of respectively 16π , 8π and 4π . Fig. 3 shows the plot of the viscosity as a function of x for each one of these cases and Fig. 4 shows the plot of the Reynolds number for them.

For all three Cases the inleat flow in Region I is considered to be fully developed with $Re_{\tau} = 550$, i.e., the same conditions as in [1]. Periodic condition is considered for the boundaries of the spamwise direction, i.e., z axis, and finally wall conditions are considered for the boundaries of the vertical direction, i.e., y axis.

METHODS - DIRECT NUMERICAL SIMULATION

In order to resolve the finest turbulent scales, the calculations of this work has been developed through Direct Numerical Simulation (DNS). To do so Nek5000 was employed, a spectral element code developed in Argonne National Laboratory (ANL). Nek5000 has been validated in references [2] and [3].

The solution of this method is given by trigonometric series, in each element a polynomial functions of up to the twelveth

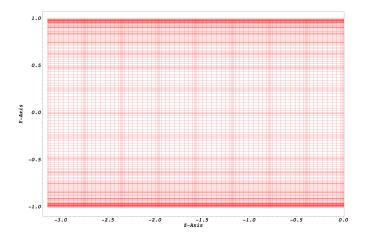

FIGURE 5: The grid employed in the simulation from half of the channel's cross section.

degree have been employed to discretize the velocity field. Fig. 5 shows an example of the grid from half of the channel's cross section. One should notice that the discretization presented by this particular area is identical through all model's domain and it is only presented half of the cross-section for better visualization of the frame.

DNS simulations are able to simulate the finest turbulent length scales without using any turbulent model. Since the present work is focused on studying the contribution of the smaller scales to the energy cascade, it is required to use DNS rather than Reynolds ge Navier-Stokes (RANS) or Large Eddy Simulations (LES), although there is a substantial growth of the computational cost.

METHODS - CONVOLUTION ANALYSIS OF THE FRICTION REYNOLDS NUMBER

The friction Reynolds number has been calculated via numerical simulations for Cases I, II and III and this result was compared to the values obtained using an existed expression from Ref. [4] valid for fully developed turbulent flows. A delay in space can be seen between Re_{τ} when comparing the simulations' results with the values yielded from the mentioned expression. This way, these results are treated as signals in the space and a convolution operation is performed over the analytical expression for fully developed turbulent flows in order to built a function that matches with the obtained values from the simulations.

To calculate the friction Reynolds number from the simulations several velocities profiles along x were obtained from the results and the viscous stress $\frac{d < U >}{dy}$ for these locations are calculated. Such values can then be applied in the set of definitions given from Eqn. 1 to Eqn. 3 following presented in order to cal-

culate Re_{τ} .

$$\tau_w = \rho v \left(\frac{d < U >}{dy} \right)_{y=0} \tag{1}$$

Where ρ is the density and τ_w is the shear stress at the wall.

$$u_{\tau} = \sqrt{\frac{\tau_w}{\rho}} \tag{2}$$

Where u_{τ} is the friction velocity. And finally,

$$Re_{\tau} = \frac{u_{\tau}\delta}{V} \tag{3}$$

Where δ is the height of the simulated channels. For all Cases studied here this is a constant parameter $\delta = 2$.

The friction Reynolds number calculated using Eqn. 3 with the numeric simulations' results is then compared with Eqn. 4 from Ref. [4], which is valid for fully developed turbulent flows.

$$Re_{\tau} = 0.09Re^{0.88} \tag{4}$$

The Reynolds numbers used to supply Eqn. 4 are those varying through x from Cases I, II and III, as presented in Fig. 4. The convolution to be performed over Eqn. 4 is given by Eqn. 5. In this equation $Re(\chi)$ stands for the analytical approximation given by Eqn. 4, $g(x-\chi)$ is a shifting function and χ is simply a dummy variable for the streamwise distance.

$$F(x) = \int_{-\infty}^{+\infty} Re_{\tau}(\chi)g(x - \chi)d\chi \tag{5}$$

As mentioned earlier, the simulated channels in the present study are divided in three Regions, as shown in Fig. ?? and a delayed function is built for each one of those. Since there is no delay in Region I, no special treatment is required for it, thus $F(x) = Re_{\tau}(x) = 550$. Differently, in Region II and III the results from the numerical experiments are delayed when compared to those from Eqn. 4 and because of that a convolution operator takes place. Since we are dealing with a delayed signal in both Regions, a decaying exponential has been used as a shifting function, as proposed in Ref. [5].

In Region II, the friction Reynolds number is a linear function given by Eqn. 6.

$$Re_{\tau}(x) = ax + 550 \tag{6}$$

Where *a* is the linear coefficient of the increasing viscosity for each one of the three cases in Region II. Using Eqn. 6 in conjunction to the definition from Eqn. 5, one may derive Eqn. 7, which is the delayed function valid for Region II of the considered Cases.

$$F(x) = \frac{a}{R^2} (e^{-R(x - \delta_{II})} - 1) + \frac{a}{R} (x - \delta_{II}) + 550$$
 (7)

Where δ_{II} is the streamwise position that Region II starts and R is named relaxing parameter and it stands for the exponential decaying constant to be used in the shifting function $g(x-\chi)$ when dealing with Region II.

Eqn. 8 is the delayed function yielded applying Eqn. 5 over Region III, where a constant friction Reynolds number Re_{τ} predicted by Eqn. 4 takes place.

$$F(x) = (20000 - \Lambda)(1 - e^{-C(x - \delta_{III})}) + \Lambda$$
 (8)

In this equation δ_{III} is the streamwise position that Region III starts, C is named contractioning parameter and it stands for the exponential decaying constant to be used in the shifting function $g(x-\chi)$ when dealing with Region III and finally $\Lambda = \frac{a}{R^2}(e^{-R(\delta_{III}-\delta_{II})}-1) + \frac{a}{R}(\delta_{III}-\delta_{II}) + 550$, represents the contribution from Regions II to the delayed signal in Region III.

In summary, Eqn. 9 express the delayed function for Re_{τ} over different Regions of the turbulence channels considered in the present work.

$$F(x) = \begin{cases} 550 & \text{(Region I)} \\ \frac{a}{R^2} (e^{-R(x - \delta_{II})} - 1) + \frac{a}{R} (x - \delta_{II}) + 550 & \text{(Region II)} \\ (20000 - \Lambda)(1 - e^{-C(x - \delta_{III})}) + \Lambda & \text{(Region III)} \end{cases}$$
(9)

RESULTS

Results from the three considered Cases in the present work are shown in this section. First, a comparison between the results in Region I from Case I with an existed data from Ref [6] is done in order to verify the model. Second, first and second order

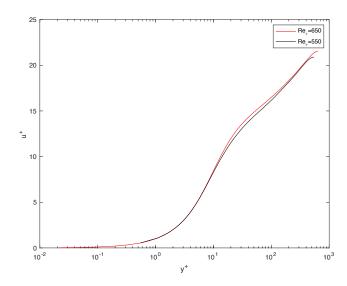

FIGURE 6: Comparing u^+ from Region I in Case I, where $Re_{\tau} = 550$, with already existed data from Ref. [6], where $Re_{\tau} = 650$.

statistics results in the close to the wall region are presented also for Case I in the interest of brevity. Third, the Re_{τ} results obtained via numerical models, through Eqn. 4 and by the derived delayed function F(x) are present. Lastly, low velocity streaks are presented in $y^+ < 10$ region from Case I and a discussion about these structures takes place.

Model verification

In order to verify the model, results from first region in Case I, where $Re_{\tau} = 550$, were compared to existed data from Ref. [6], DNS results of a turbulence channel with $Re_{\tau} = 650$ is found. Fig. 6 shows the u^+ versus y^+ plots for both results, while Fig. 7 shows < uu > versus y^+ plots. These graphs shows that the results from both simulations follows the expected behaviour, this fact grants confidence to the models used in the present work.

First and second order statistics

The averaging time employed to obtain statistics results for Case I was judged sufficient since it allowed the solution to reach near perfect symmetry. Furthermore, to reduce this time spatial average has been taken over the spanwise direction, since the flow is homogeneous in this direction.

Fig. 8 shows how < u > profile develops along the channel in Case I. From this result we can clearly see that the viscous stress at the wall $\left(\frac{d < U >}{dy}\right)_{y=0}$ gets more pronounced as we move in the streamwise direction. This result makes sense, since in Region II the viscosity starts decreasing linearly, as shown through Fig 3, causing the viscous effects to become more

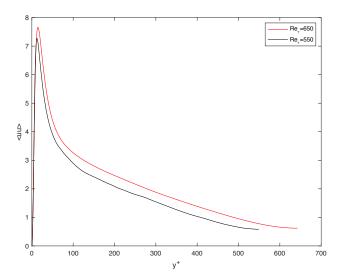

FIGURE 7: Comparing < uu > from Region I in Case I, where $Re_{\tau} = 550$, with already existed data from Ref. [6], where $Re_{\tau} = 650$.

pronouced. This fact also explains why the turbulent boundary layer $(y^+ = 30)$ starts getting closer to the wall in this same range, fact also presented in Fig. 8. Moreover, after a certain position in x, the bouldary layer reaches a constant height from the wall, this fact also makes sense once in Region III the viscosity becomes constant, not causing a change in the viscous stress anymore.

Meanwhile, Fig. 9 shows < uu > profile development throughtout the streamwise direction also for Case I. As we move foward in the streamwise direction in this plot, the peak of < uu > increases and gets closer to the wall. This result is also in good agreement with what is expected, since the turbulence must increase in Region II.

The delayed friction Reynolds number

Figs. 10-12 presents three different friction Reynolds numbers for the cases considered here: first, the values obtained by Eqn. 4, which is an approximation existed in Ref. [4] and it is valid for fully developed turbulent flows, second, the numerical result obtained via DNS simulation using Nek5000 and finally, the result from the delayed function presented earlier in Eqn. 9

Unfourtunantly, it was not possible to run Cases II and III the same long, thus the results for this simulations a
